Abstract

We present αKanren, an embedding of nominal logic programming in Scheme. αKanren is inspired by αProlog and MLSOS, and allows programmers to easily write interpreters, type inferencers, and other programs that must reason about scope and binding. αKanren subsumes the functionality, syntax, and implementation of miniKanren, itself an embedding of logic programming in Scheme.

We present the *complete* implementation of αKanren, written in portable R^5RS Scheme. In addition to the implementation, we provide introductions to miniKanren and αKanren, and several example programs, including a type inferencer for the simply typed λ-calculus.

Categories and Subject Descriptors D.1.6 [*Programming Techniques*]: Logic Programming; D.1.1 [*Programming Techniques*]: Applicative (Functional) Programming

General Terms Languages

Keywords αKanren, αProlog, MLSOS, Scheme, miniKanren, logic programming, nominal logic, nominal unification

1. Introduction

We present a complete implementation in R^5RS Scheme of αKanren, which extends the miniKanren logic programming language (Byrd and Friedman 2006) with operators for *nominal logic programming*. αKanren was inspired by αProlog (Cheney 2004; Cheney and Urban 2004) and MLSOS (Lakin and Pitts 2007), and their use of nominal logic (Pitts 2003) to solve a class of problems more elegantly than is possible with conventional logic programming. The purpose of this paper is to present a readily understandable and hackable embedding of nominal logic programming in portable Scheme, and to make more Schemers aware of the interesting and useful notions of nominal logic.

Like αProlog and MLSOS, αKanren allows programmers to explicitly manage names and bindings, making it easier to write interpreters, type inferencers, and other programs that must reason about scope. αKanren also eases the burden of implementing a language from its structural operational semantics, since the requisite side-conditions can often be trivially encoded in nominal logic.

A standard class of such side conditions is to state that a certain variable name cannot occur free in a particular expression. It is a simple matter to check for free occurrences of a variable name in a fully-instantiated term, but in a logic program the term might contain unbound logic variables. At a later point in the program those variables might be instantiated to terms containing the variable name in question. Also, when the writer of semantics employs the equality symbol, the writer generally has in mind that two terms are the same, but what they really mean is that the two terms are the same *up to α-equivalence*, as in the variable hygiene convention popularized by Barendregt (1984). As functional programmers, we would never quibble with the statement: $\lambda x.x = \lambda y.y$, yet without the implicit assumption that one can rename variables using α-conversion, we would have to forego this obvious equality. And again, if either expression contains an unbound logic variable, it is impossible to perform a full parallel tree walk to determine if the two expressions are α-equivalent: at least part of the tree walk must be deferred until one or both expressions are fully instantiated.

Just as hygienic macros (Kohlbecker et al. 1986) allow Scheme programmers to avoid hygiene concerns before run time, nominal logic allows programmers to address hygiene concerns at run time. Schemers have been thinking about issues of hygiene for at least two decades; we think the Scheme community can both contribute to, and learn from, the relatively new field of nominal logic.

We proceed as follows. Section 2 provides a brief review of miniKanren, an embedding of logic programming in Scheme; miniKanren is similar to standard Prolog in that it does not include nominal logic operators. In Section 3, we extend miniKanren to arrive at the αKanren language, and explain how these extensions correspond to the ideas of nominal logic programming. We give several example programs and their results, including non-naive β-substitution and a type inferencer for the simply typed λ-calculus. In Section 4 we define the nominal unifier, which is the heart of nominal logic programming. In the appendices we define and demonstrate a simple pattern matcher, followed by the remainder of the αKanren implementation.

2. miniKanren Refresher

αKanren extends miniKanren, an embedding of logic programming in Scheme. In this section we briefly review the miniKanren language; readers already familiar with miniKanren can safely skip to Section 3, while those wishing to learn more about the language should see Byrd and Friedman (2006) (from which this refresher was adapted) and Friedman et al. (2005).

Our code uses the following typographic conventions. Lexical variables are in *italic*, forms are in **boldface**, and quoted symbols are in sans serif. By our convention, names of relations end with a superscript o—for example $subst^o$, which is entered as substo. Relational operators do not follow this convention: $\equiv$ (entered as ==), **cond**^{e} (entered as conde), and **exists** (changed from **fresh**, since we use **fresh** in the next section). Similarly, (**run**^{5} (q) *body*) and (**run*** (q) *body*) are entered as (run 5 (q) body) and (run* (q) body), respectively.

miniKanren extends Scheme with three operators: $\equiv$, **cond**^{e}, and **exists**. There is also **run**, which serves as an interface between Scheme and miniKanren, and whose value is a list.

exists, which syntactically looks like **lambda**, introduces new variables into its scope; $\equiv$ unifies two terms. Thus

(**exists** (x y z) ($\equiv$ x z) ($\equiv$ 3 y))

would associate x with z and y with 3. This, however, is not a legal miniKanren program—we must wrap a **run** around the entire expression.

(**run**^{1} (q) (**exists** (x y z) ($\equiv$ x z) ($\equiv$ 3 y))) $\Rightarrow$ ($._0$)

The value returned is a list containing the single value $._0$; we say that $._0$ is the *reified value* of the unbound variable q. q also remains unbound in

(**run**^{1} (q) (**exists** (x y) ($\equiv$ x q) ($\equiv$ 3 y))) $\Rightarrow$ ($._0$)

We can get back other values, of course.

(**run**^{1} (y)	(**run**^{1} (q)	(**run**^{1} (y)
(**exists** (x z)	(**exists** (x z)	(**exists** (x y)
($\equiv$ x z)	($\equiv$ x z)	($\equiv$ 4 x)
($\equiv$ 3 y)))	($\equiv$ 3 z)	($\equiv$ x y))
	($\equiv$ q x)))	($\equiv$ 3 y))

Each of these examples returns (3); in the rightmost example, the y introduced by **exists** is different from the y introduced by **run**. **run** can also return the empty list, indicating that there are no values.

(**run**^{1} (x) ($\equiv$ 4 3)) $\Rightarrow$ ()

We use **cond**^{e} to get several values—syntactically, **cond**^{e} looks like **cond** but without $\Rightarrow$ or **else**. For example,

(**run**^{2} (q)
  (**exists** (x y z)
    (**cond**^{e}
      (($\equiv$ '(,x ,y ,z ,x) q))
      (($\equiv$ '(,z ,y ,x ,z) q)))))) $\Rightarrow$

(($._0$ $._1$ $._2$ $._0$) ($._0$ $._1$ $._2$ $._0$))

Although the two **cond**^{e} clauses are different, the values returned are identical. This is because distinct reified unbound logic variables are assigned distinct subscripts, increasing from left to right—the numbering starts over again from zero within each value, which is why the reified value of x is $._0$ in the first value but $._2$ in the second value.

The superscript 2 denotes the maximum length of the resultant list. If the superscript $*$ is used, then there is no maximum imposed. This can easily lead to infinite loops:

(**run*** (q)
  (**let** *loop* ()
    (**cond**^{e}
      (($\equiv$ #f q))
      (($\equiv$ #t q))
      ((*loop*)))))

Had the $*$ been replaced by a non-negative integer n, then a list of n alternating #f's and #t's would be returned. The **cond**^{e} succeeds while associating q with #f, which accounts for the first value. When getting the second value, the second **cond**^{e}-clause is tried, and the association made between q and #f is forgotten—we say that q has been *renewed*. In the third **cond**^{e}-clause, q is renewed once again.

We now look at several interesting examples that rely on any^o, which tries g an unbounded number of times.

(**define** any^o
  (λ (g)
    (**cond**^{e}
      (g)
      ((any^o g)))))

Consider the first example

(**run*** (q)
  (**cond**^{e}
    ((any^o ($\equiv$ #f q)))
    (($\equiv$ #t q))))

which does not terminate because the call to any^o succeeds an unbounded number of times. If $*$ were replaced by 5, then we would get (#t #f #f #f #f). (The user should not be concerned with the order in which values are returned.)

Now consider

(**run**^{10} (q)
  (any^o
    (**cond**^{e}
      (($\equiv$ 1 q))
      (($\equiv$ 2 q))
      (($\equiv$ 3 q))))) $\Rightarrow$

(1 2 3 1 2 3 1 2 3 1)

Here the values 1, 2, and 3 are interleaved; our use of any^o ensures that this sequence will be repeated indefinitely.

Even if some **cond**^{e}-clauses loop indefinitely, other **cond**^{e}-clauses can contribute to the values returned by a **run** expression. (We are not concerned with Scheme expressions looping indefinitely, however.) For example,

(**run**^{3} (q)
  (**let** (($never^o$ (any^o ($\equiv$ #f #t))))
    (**cond**^{e}
      (($\equiv$ 1 q))
      ($never^o$)
      ((**cond**^{e}
        (($\equiv$ 2 q))
        ($never^o$)
        (($\equiv$ 3 q))))))))

returns (1 2 3); replacing **run**^{3} with **run**^{4} would cause divergence, however, since there are only three values, and since $never^o$ would loop indefinitely.

3. Introduction to αKanren

αKanren extends the miniKanren language with two additional operators, **fresh** and # (entered as `hash`), and one term constructor, $\bowtie$ (entered as `tie`).

fresh, which syntactically looks like **exists**, introduces new *noms* into its scope. (Noms are also called "names" or "atoms", overloaded terminology which we avoid.) Conceptually, a nom represents a variable name[1]; however, a nom behaves more like a constant than a variable, since it only unifies with itself or with an unbound variable.

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a)\ (\equiv a\ a))) \Rightarrow (\text{\_}_0)$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a)\ (\equiv a\ 5))) \Rightarrow ()$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a\ b)\ (\equiv a\ b))) \Rightarrow ()$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (b)\ (\equiv b\ q))) \Rightarrow (\mathsf{b}_0)$

A reified nom is subscripted in the same fashion as a reified variable, but the name with which the nom is declared is used instead of an underscore (_)—hence the (b_0) in the final example above. **fresh** forms can be nested, which may result in noms being shadowed.

```
(run* (q)
  (exists (x y z)
    (fresh (a)
      (≡ x a)
      (fresh (a b)
        (≡ y a)
        (≡ `(,x ,y ,z ,a ,b) q))))) ⇒
```

$((\mathsf{a}_0\ \mathsf{a}_1\ \text{\_}_0\ \mathsf{a}_1\ \mathsf{b}_0))$

Here a_0 and a_1 represent different noms, which will not unify with each other.

$\bowtie$ is a *term constructor* used to limit the scope of a nom within a term (any value that can contain variables and noms).

```
(define-syntax ⋈
  (syntax-rules ()
    ((_ a t) `(tie ,a ,t))))
```

Terms constructed using $\bowtie$ are called *binders*. In the term created by the expression $(\bowtie a\ t)$, all occurrences of the nom a within term t are considered bound. We refer to the term t as the *body* of $(\bowtie a\ t)$, and to the nom a as being in *binding position*. The $\bowtie$ constructor does not create noms; rather, it delimits the scope of existing noms, already introduced using **fresh**.

For example, consider this **run*** expression.

```
(run* (q)
  (fresh (a b)
    (≡ (⋈ a `(foo ,a 3 ,b)) q))) ⇒
```

$((\mathsf{tie}\ \mathsf{a}_0\ (\mathsf{foo}\ \mathsf{a}_0\ 3\ \mathsf{b}_0)))$

The tagged list $(\mathsf{tie}\ \mathsf{a}_0\ (\mathsf{foo}\ \mathsf{a}_0\ 3\ \mathsf{b}_0))$ is the reified value of the term constructed using $\bowtie$. (The tag name `tie` is a pun—the bowtie $\bowtie$ is the "tie that binds.") The nom whose reified value is a_0 occurs bound within the term $(\mathsf{tie}\ \mathsf{a}_0\ (\mathsf{foo}\ \mathsf{a}_0\ 3\ \mathsf{b}_0))$ while b_0 occurs free in that same term.

introduces a *freshness constraint* (henceforth referred to as simply a *constraint*). The expression $(\#\ a\ t)$ asserts that the nom a does *not* occur free in term t—if a occurs free in t, then $(\#\ a\ t)$ fails. Furthermore, if t contains an

---

[1] Less commonly, a nom represents a non-variable entity. For example, a nom may represent a channel name in the π-calculus—see Cheney (2004) for details.

unbound variable x, and some later unification involving x results in a occurring free in t, then that unification fails.

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a)\ (\equiv\ `(3\ ,a\ \mathtt{\#t})\ q)\ (\#\ a\ q))) \Rightarrow ()$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a)\ (\#\ a\ q)\ (\equiv\ `(3\ ,a\ \mathtt{\#t})\ q))) \Rightarrow ()$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a\ b)\ (\#\ a\ (\bowtie\ b\ a)))) \Rightarrow ()$

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a)\ (\#\ a\ (\bowtie\ a\ a)))) \Rightarrow (\text{\_}_0)$

```
(run* (q)
  (exists (x y z)
    (fresh (a)
      (# a x)
      (≡ `(,y ,z) x)
      (≡ `(,x ,a) q)))) ⇒
```

$((((\text{\_}_0\ \text{\_}_1)\ \mathsf{a}_0)\ :\ ((\mathsf{a}_0\ \cdot\ \text{\_}_0)\ (\mathsf{a}_0\ \cdot\ \text{\_}_1))))$

In the fourth example, the constraint $(\#\ a\ (\bowtie\ a\ a))$ is not violated because a does not occur free in $(\bowtie\ a\ a)$. In the final example, the partial instantiation of x causes the constraint introduced by $(\#\ a\ x)$ to be "pushed down" onto the unbound variables y and z. The answer comprises two parts, separated by a colon and enclosed in an extra set of parentheses: the reified value of $((y\ z)\ a)$ and a list of reified constraints indicating that a cannot occur free in either y or z.

The notion of a constraint is prominent in the standard definition of α-equivalence (Stoy 1979):

$$\lambda a.M \equiv_\alpha \lambda b.[b/a]M \text{ where } b \text{ does not occur free in } M.$$

In αKanren this constraint is expressed as $(\#\ b\ M)$. We shall revisit the connection between constraints and α-equivalence shortly.

We now extend the standard notion of unification to that of *nominal unification* (Urban et al. 2004), which equates α-equivalent binders. Consider this **run*** expression.

$(\mathbf{run}^*\ (q)\ (\mathbf{fresh}\ (a\ b)\ (\equiv\ (\bowtie\ a\ a)\ (\bowtie\ b\ b)))) \Rightarrow (\text{\_}_0)$

Although a and b are distinct noms, $(\equiv\ (\bowtie\ a\ a)\ (\bowtie\ b\ b))$ succeeds. According to the rules of nominal unification, the binders $(\bowtie\ a\ a)$ and $(\bowtie\ b\ b)$ represent the same term, and therefore unify.

The reader may suspect that, as in the definition of α-equivalence given above, nominal unification uses substitution to equate binders

$$(\bowtie\ a\ a) \equiv_\alpha (\bowtie\ b\ [b/a]a)$$

however, this is not the case.

Unfortunately, naive substitution does not preserve α-equivalence of terms, as shown in the following example given by Urban et al. (2004). Consider the α-equivalent terms $(\bowtie\ a\ b)$ and $(\bowtie\ c\ b)$; replacing all free occurrences of b with a in both terms yields $(\bowtie\ a\ a)$ and $(\bowtie\ c\ a)$, which are no longer α-equivalent.

Rather than using capture-avoiding substitution to address this problem, nominal logic uses the simple and elegant notion of a *nom swap*. Instead of performing a unidirectional substitution of a for b, the unifier exchanges all occurrences of a and b within a term, regardless of whether those noms appear free, bound, or in the binding position of a $\bowtie$-constructed binder. Applying the swap $(a\ b)$ to $(\bowtie\ a\ b)$ and $(\bowtie\ c\ b)$ yields the α-equivalent terms $(\bowtie\ b\ a)$ and $(\bowtie\ c\ a)$.

When unifying $(\bowtie\ a\ a)$ and $(\bowtie\ b\ b)$ in the **run*** expression above, the nominal unifier first creates the swap $(a\ b)$ containing the noms in the binding positions of the two

terms. The unifier then applies this swap to $(\bowtie\ a\ a)$, yielding $(\bowtie\ b\ b)$ (or equivalently, applies the swap to $(\bowtie\ b\ b)$, yielding $(\bowtie\ a\ a)$). Obviously $(\bowtie\ b\ b)$ unifies with itself, according to the standard rules of unification, and thus the nominal unification succeeds.

Of course, the terms being unified might contain unbound variables. In the simple example

$(\textbf{run}^*\ (q)\ (\textbf{fresh}\ (a\ b)\ (\equiv\ (\bowtie\ a\ q)\ (\bowtie\ b\ b)))) \Rightarrow (\mathsf{a}_0)$

the swap $(a\ b)$ can be applied to $(\bowtie\ b\ b)$, yielding $(\bowtie\ a\ a)$. The terms $(\bowtie\ a\ a)$ and $(\bowtie\ a\ q)$ are then unified, associating q with a. However, in some cases a swap cannot be performed until a variable has become at least partially instantiated. For example, in the first call to $\equiv$ in

$(\textbf{run}^*\ (q)$
$\quad(\textbf{fresh}\ (a\ b)$
$\quad\quad(\textbf{exists}\ (x\ y)$
$\quad\quad\quad(\equiv\ (\bowtie\ a\ (\bowtie\ a\ x))\ (\bowtie\ a\ (\bowtie\ b\ y)))$
$\quad\quad\quad(\equiv\ \text{`}(,x\ ,y)\ q))))$

the unifier cannot apply the swap $(a\ b)$ to either x or y, since they are both unbound. (The unifier does not generate a swap for the outer binders, since they have the same nom in their binding positions.)

Nominal unification solves this problem by introducing the notion of a *suspension*, which is a record of *delayed swaps* that may be applied later. We represent a suspension using the susp data structure, which comprises a list of suspended swaps and a variable.

$$(\mathsf{susp}\ ((a_n\ b_n)\ \ldots\ (a_1\ b_1))\ x)$$

The swaps are deferred until the variable x is instantiated (at least partially); at this point the swaps are applied to the instantiated portion of the term associated with x. Swaps are applied from right to left; that is, the result of applying the swaps to a term t can be determined by first exchanging all occurrences of noms a_1 and b_1 within t, then exchanging a_2 and b_2 within the resulting term, and continuing in this fashion until finally exchanging a_n with b_n.

Now that we have the notion of a suspension, we can define equality on binders (adapted from Urban et al. 2004):

$(\bowtie\ a\ M)$ and $(\bowtie\ b\ N)$ are α-equivalent if and only if a and b are the same nom and M is α-equivalent to N, or if $(\mathsf{susp}\ ((a\ b))\ M)$ is α-equivalent to N and $(\#\ b\ M)$.

The side condition $(\#\ b\ M)$ is necessary, since if b occurred free in M, then b would be inadvertently captured (and replaced with a) by the suspension $(\mathsf{susp}\ ((a\ b))\ M)$.

Having defined equality on binders, we can examine the result of the previous $\textbf{run}^*$ expression.

$(\textbf{run}^*\ (q)$
$\quad(\textbf{fresh}\ (a\ b)$
$\quad\quad(\textbf{exists}\ (x\ y)$
$\quad\quad\quad(\equiv\ (\bowtie\ a\ (\bowtie\ a\ x))\ (\bowtie\ a\ (\bowtie\ b\ y)))$
$\quad\quad\quad(\equiv\ \text{`}(,x\ ,y)\ q)))) \Rightarrow$

$(((((\mathsf{susp}\ ((\mathsf{a}_0\ \mathsf{b}_0))\ \_0)\ \_0)\ :\ ((\mathsf{a}_0\ \cdot\ \_0))))$

The first call to $\equiv$ applies the swap $(a\ b)$ to the unbound variable y, and then associates the resulting suspension $(\mathsf{susp}\ ((a\ b))\ y)$ with x. Of course, the unifier could have applied the swap to x instead of y, resulting in a symmetric answer. The freshness constraint states that the nom a can never occur free within y, as required by the definition of binder equivalence.

Here is a translation of a quiz presented in Urban et al. (2004), demonstrating some of the finer points of nominal unification.

$(\textbf{run}^*\ (q)$
$\quad(\textbf{fresh}\ (a\ b)$
$\quad\quad(\textbf{exists}\ (x\ y)$
$\quad\quad\quad(\textbf{cond}^e$
$\quad\quad\quad\quad((\equiv\ (\bowtie\ a\ (\bowtie\ b\ \text{`}(,x\ ,b)))\ (\bowtie\ b\ (\bowtie\ a\ \text{`}(,a\ ,x)))))$
$\quad\quad\quad\quad((\equiv\ (\bowtie\ a\ (\bowtie\ b\ \text{`}(,y\ ,b)))\ (\bowtie\ b\ (\bowtie\ a\ \text{`}(,a\ ,x)))))$
$\quad\quad\quad\quad((\equiv\ (\bowtie\ a\ (\bowtie\ b\ \text{`}(,b\ ,y)))\ (\bowtie\ b\ (\bowtie\ a\ \text{`}(,a\ ,x)))))$
$\quad\quad\quad\quad((\equiv\ (\bowtie\ a\ (\bowtie\ b\ \text{`}(,b\ ,y)))\ (\bowtie\ a\ (\bowtie\ a\ \text{`}(,a\ ,x))))))$
$\quad\quad\quad\quad(\equiv\ \text{`}(,x\ ,y)\ q)))) \Rightarrow$

$((\mathsf{a}_0\ \mathsf{b}_0)$
$\ (\_0\ (\mathsf{susp}\ ((\mathsf{a}_0\ \mathsf{b}_0))\ \_0))$
$\ ((\_0\ (\mathsf{susp}\ ((\mathsf{b}_0\ \mathsf{a}_0))\ \_0))\ :\ ((\mathsf{b}_0\ \cdot\ \_0))))$

The first $\textbf{cond}^e$ clause fails, since x cannot be associated with both a and b. The second clause succeeds, associating x with a and y with b. The third clause applies the swap $(a\ b)$ to $(\bowtie\ a\ (a\ x))$, yielding $(\bowtie\ b\ (b\ (\mathsf{susp}\ ((a\ b))\ x)))$. This term is then unified with $(\bowtie\ b\ (b\ y))$, associating y with the suspension $(\mathsf{susp}\ ((a\ b))\ x)$. The fourth clause should look familiar—it is similar to the previous $\textbf{run}^*$ expression.

We can interpret the successful unification of binders $(\bowtie\ a\ a)$ and $(\bowtie\ b\ b)$ as showing that the λ-calculus terms $\lambda a.a$ and $\lambda b.b$ are identical, up to α-equivalence. We need not restrict our interpretation to λ terms, however, since other scoping mechanisms have similar properties. For example, the same successful unification also shows that $\forall a.a$ and $\forall b.b$ are equivalent in first-order logic, and similarly, that $\exists a.a$ and $\exists b.b$ are equivalent.

We can tag terms in order to disambiguate their interpretation. For example, this program shows that $\lambda a.\lambda b.a$ and $\lambda c.\lambda d.c$ are equivalent.

$(\textbf{run}^*\ (q)$
$\quad(\textbf{exists}\ (t\ u)$
$\quad\quad(\textbf{fresh}\ (a\ b\ c\ d)$
$\quad\quad\quad(\equiv\ \text{`}(\mathsf{lam}\ ,(\bowtie\ a\ \text{`}(\mathsf{lam}\ ,(\bowtie\ b\ \text{`}(\mathsf{var}\ ,a)))))\ t)$
$\quad\quad\quad(\equiv\ \text{`}(\mathsf{lam}\ ,(\bowtie\ c\ \text{`}(\mathsf{lam}\ ,(\bowtie\ d\ \text{`}(\mathsf{var}\ ,c)))))\ u)$
$\quad\quad\quad(\equiv\ t\ u)))) \Rightarrow$

$(\_0)$

Of course, not all λ-calculus terms are equivalent.

$(\textbf{run}^*\ (q)$
$\quad(\textbf{exists}\ (t\ u)$
$\quad\quad(\textbf{fresh}\ (a\ b\ c\ d)$
$\quad\quad\quad(\equiv\ \text{`}(\mathsf{lam}\ ,(\bowtie\ a\ \text{`}(\mathsf{lam}\ ,(\bowtie\ b\ \text{`}(\mathsf{var}\ ,a)))))\ t)$
$\quad\quad\quad(\equiv\ \text{`}(\mathsf{lam}\ ,(\bowtie\ c\ \text{`}(\mathsf{lam}\ ,(\bowtie\ d\ \text{`}(\mathsf{var}\ ,d)))))\ u)$
$\quad\quad\quad(\equiv\ t\ u)))) \Rightarrow$

$()$

Here $(\equiv\ t\ u)$ fails, showing that $\lambda a.\lambda b.a$ and $\lambda c.\lambda d.d$ are not α-equivalent.

3.1 Non-naive Substitution

We now consider a simple, but useful, nominal logic program adapted from Cheney and Urban (2004) that performs capture-avoiding substitution (that is, β-substitution). $subst^o$ implements the relation $[new/a]e = out$ where e, new, and out are tagged lists representing λ-calculus terms, and where a is a nom representing a variable name. (We refer the interested reader to Cheney and Urban for a full description of $subst^o$.)

```
(define subst°
  (λ (e new a out)
    (cond^e
      ((≡ '(var ,a) e) (≡ new out))
      ((exists (y)
         (≡ '(var ,y) e)
         (≡ '(var ,y) out)
         (# a y)))
      ((exists (rator ratorres rand randres)
         (≡ '(app ,rator ,rand) e)
         (≡ '(app ,ratorres ,randres) out)
         (subst° rator new a ratorres)
         (subst° rand new a randres)))
      ((exists (body bodyres)
         (fresh (c)
           (≡ '(lam ,(⋈ c body)) e)
           (≡ '(lam ,(⋈ c bodyres)) out)
           (# c a)
           (# c new)
           (subst° body new a bodyres)))))))))
```

The first $subst^o$ example shows that $[b/a]\lambda a.ab \equiv_\alpha \lambda c.cb$.

```
(run* (q)
  (fresh (a b)
    (subst°
      '(lam ,(⋈ a '(app (var ,a) (var ,b)))) '(var ,b) a q))) ⇒
```

$$((\text{lam (tie } c_0 \text{ (app (var } c_0) \text{ (var } b_0)))))$$

Naive substitution would have produced $\lambda b.bb$ instead.

This second example shows that $[a/b]\lambda a.b \equiv_\alpha \lambda c.a$.

```
(run* (x)
  (fresh (a b)
    (subst° '(lam ,(⋈ a '(var ,b))) '(var ,a) b x))) ⇒
```

$$((\text{lam (tie } c_0 \text{ (var } a_0))))$$

Naive substitution would have produced $\lambda a.a$.

3.2 Type Inferencer for Simply Typed λ-calculus

Let us consider a second non-trivial αKanren example: a type inferencer for the simply typed λ-calculus (also adapted from Cheney and Urban 2004). typ^o relates a λ-calculus term e to its type te in type environment g.

```
(define typ°
  (λ (g e te)
    (cond^e
      ((exists (x)
         (≡ '(var ,x) e)
         (lookup° x te g)))
      ((exists (rator trator rand trand)
         (≡ '(app ,rator ,rand) e)
         (≡ '(→ ,trand ,te) trator)
         (typ° g rator trator)
         (typ° g rand trand)))
      ((exists (ê tê trand ĝ)
         (fresh (b)
           (≡ '(lam ,(⋈ b ê)) e)
           (≡ '(→ ,trand ,tê) te)
           (# b g)
           (≡ '((,b . ,trand) . ,g) ĝ)
           (typ° ĝ ê tê)))))))))
```

The $lookup^o$ helper relation finds the type tx associated with the type variable x in the current type environment g.

```
(define lookup°
  (λ (x tx g)
    (exists (a d)
      (≡ '(,a . ,d) g)
      (cond^e
        ((≡ '(,x . ,tx) a))
        ((exists (x̂ tx̂)
           (≡ '(,x̂ . ,tx̂) a)
           (# x x̂)
           (lookup° x tx d)))))))))
```

The first typ^o example shows that $\lambda c.\lambda d.c$ has type $(\alpha \rightarrow (\beta \rightarrow \alpha))$.

```
(run* (q)
  (fresh (c d)
    (typ° '() '(lam ,(⋈ c '(lam ,(⋈ d '(var ,c))))) q))) ⇒
```

$$((\rightarrow\ _0\ (\rightarrow\ _1\ _0)))$$

The second example shows that self-application doesn't type check, since the nominal unifier uses the occurs check (Lloyd 1987).

```
(run* (q)
  (fresh (c)
    (typ° '() '(lam ,(⋈ c '(app (var ,c) (var ,c)))) q))) ⇒
```

()

The final example is the most interesting, since it searches for terms that inhabit the type $(\text{int} \rightarrow \text{int})$.

```
(run² (q) (typ° '() q '(→ int int))) ⇒
```

```
((lam (tie b₀ (var b₀)))
 (lam (tie b₀ (app (lam (tie b₁ (var b₁))) (var b₀)))))
```

The first two terms found are $\lambda b.b$ and $\lambda b.(\lambda a.a)b$.

This ends the introduction to αKanren. For additional simple examples of nominal logic programming, we suggest Cheney (2004), Cheney and Urban (2004), Urban et al. (2004), and Lakin and Pitts (2007), which are also excellent choices for understanding the theory of nominal logic. Next we discuss our implementation of nominal unification.

4. Nominal Unification

Nominal unification occurs in two distinct phases: the first processes equations, while the second processes constraints. The first phase takes a set of equations ϵ and transforms it into a substitution σ and a set of unresolved constraints δ. The second phase combines δ with any existing constraints, then applies the substitution σ to the combined constraints. Finally, the unifier transforms these unprocessed constraints into a set of processed constraints ∇, and returns the list $(\sigma\ \nabla)$ as a *package*.

Nominal unification uses several data structures. A set of equations ϵ is represented as a list of pairs of terms. A substitution σ is represented as an association list of variables to terms. A set of constraints δ is represented as a list of pairs associating noms to terms; a ∇ is a δ in which all terms are unbound variables. In a substitution, a variable may have at most one association. In a δ (and therefore in a ∇) a nom may have multiple associations.

We represent a variable as a suspension containing an empty list of swaps. Several functions reconstruct suspensions that represent variables. However, our implementation of nominal unification assumes that variables can be compared using *eq?*.

In order to ensure that a variable is always *eq?* to itself, regardless of how many times it is reconstructed, we use a **letrec** trick: a suspension representing a variable contains a

procedure of zero arguments (a *thunk*) that, when invoked, returns the suspension, thus maintaining the desired *eq?*-ness property. (In the text we conflate variables with their associated thunks.)

```
(define var
  (λ ()
    (letrec ((s (list 'susp '() (λ () s))))
      s)))
```

unify attempts to equate terms u and v in the context of a package $(\sigma \nabla)$. *unify* applies σ to u and v, adds the pair of resulting terms to σ to obtain a new set of equations ϵ, and then calls *apply-σ-rules* on ϵ. *apply-σ-rules* either successfully completes the first phase of nominal unification by returning a new σ and δ, or invokes the failure continuation *fk*. (*fk* is used as a jump-out continuation, as in Lisp's *catch* (Steele Jr. 1990).) In the second phase of nominal unification, *unify* applies σ to the union of ∇ and δ to obtain a new set of constraints that is then passed to *apply-∇-rules*.
(We use **mv-let** to deconstruct a list of values. See Appendix A for its implementation and a simple example of its use.).

```
(define unify
  (λ (u v p)
    (call/cc
      (λ (fk)
        (mv-let ((σ ∇) p)
          (let ((ε '(,(apply-subst σ '(,u . ,v)) . ,σ)))
            (mv-let ((σ δ) (apply-σ-rules ε fk))
              (let* ((δ (apply-subst σ (δ-union ∇ δ)))
                     (∇ (apply-∇-rules δ fk)))
                '(,σ ,∇)))))))))
```

apply-σ-rules and *apply-∇-rules* are simple recursive functions that exist only to combine results returned by *one-step*.

```
(define apply-σ-rules
  (λ (ε fk)
    (cond
      ((null? ε) '(,empty-σ ,empty-δ))
      (else
        (mv-let ((ε σ δ) (one-step σ-rules ε fk))
          (mv-let ((σ̂ δ̂) (apply-σ-rules ε fk))
            '(,(compose-subst σ σ̂) ,(δ-union δ̂ δ))))))))
```

```
(define apply-∇-rules
  (λ (δ fk)
    (cond
      ((null? δ) empty-∇)
      (else
        (mv-let ((δ ∇) (one-step ∇-rules δ fk))
          (δ-union ∇ (apply-∇-rules δ fk)))))))
```

(*empty-σ*, *empty-δ*, and *empty-∇* are defined in Appendix B.)

one-step takes three arguments: a function *rules* (either *σ-rules* or *∇-rules*); a list of constraints c^*; and a failure continuation *fk*. (**pmatch** is explained in Appendix A.)

```
(define one-step
  (λ (rules c* fk)
    (let loop ((tried '()) (untried c*))
      (pmatch untried
        (() (fk #f))
        ((,c . ,untried)
         (or (rules c (append tried untried))
             (loop '(,c . ,tried) untried)))))))
```

A constraint is either an equation or an (unprocessed) freshness constraint. *one-step* attempts to apply *rules* to the constraints in c^* until a constraint matches a clause in *rules*.

one-step passes to *rules* not only the current constraint c but also the context containing all the other constraints, both tried and untried.

In both *σ-rules* and *∇-rules* we use *untagged?* to distinguish untagged pairs from specially tagged pairs that represent binders, noms, and suspensions.

```
(define untagged?
  (λ (x)
    (not (memv x '(tie nom susp)))))
```

Here are the transformation rules of the nominal unification algorithm, based on the rules in Urban et al. (2004).

```
(define σ-rules
  (λ (eqn r)
    (pmatch eqn
      ((,c . ,ĉ)
       (guard (not (pair? c)) (equal? c ĉ))
       '(,r ,empty-σ ,empty-δ))
      (((tie ,a ,t) . (tie ,â ,t̂))
       (guard (eq? a â))
       '(((,t . ,t̂) . ,r) ,empty-σ ,empty-δ))
      (((tie ,a ,t) . (tie ,â ,t̂))
       (guard (not (eq? a â)))
       (let ((û (apply-π '((,a ,â)) t̂)))
         '(((,t . ,û) . ,r) ,empty-σ ((,a . ,t̂)))))
      (((nom _) . (nom _))
       (guard (eq? (car eqn) (cdr eqn)))
       '(,r ,empty-σ ,empty-δ))
      (((susp ,π ,x) . (susp ,π̂ ,x̂))
       (guard (eq? (x) (x̂)))
       (let ((δ (map (λ (a) '(,a . ,(x)))
                     (disagreement-set π π̂))))
         '(,r ,empty-σ ,δ)))
      (((susp ,π ,x) . ,t)
       (guard (not (occurs√ (x) t)))
       (let ((σ '(((,x) . ,(apply-π (reverse π) t)))))
         '(,(apply-subst σ r) ,σ ,empty-δ)))
      ((,t . (susp ,π ,x))
       (guard (not (occurs√ (x) t)))
       (let ((σ '(((,x) . ,(apply-π (reverse π) t)))))
         '(,(apply-subst σ r) ,σ ,empty-δ)))
      (((,t₁ . ,t₂) . (,t̂₁ . ,t̂₂))
       (guard (untagged? t₁) (untagged? t̂₁))
       '(((,t₁ . ,t̂₁) (,t₂ . ,t̂₂) . ,r) ,empty-σ ,empty-δ))
      (else #f))))
```

Clauses two and three in *σ-rules* implement α-equivalence of binders, as defined in Section 3. Clause five unifies two suspensions that have the same variable; in this case, *σ-rules* creates as many new freshness constraints as there are noms in the *disagreement set* (defined below) of the suspensions' swaps. Clauses six and seven are similar: each clause unifies a suspension containing a variable x and a list of swaps π with a term t. *σ-rules* creates a singleton substitution associating x with the result of applying the swaps in π to t in *reverse order*, with the newest swap in π applied first. This singleton substitution is applied to the context r.

apply-π applies a list of swaps π to a term v. If v is a nom, then the swaps in π are applied, with the oldest swap applied first. If v is a suspension with a list of swaps $\hat{\pi}$ and variable x, then the swaps in π are added to the swaps in $\hat{\pi}$. If the new list of swaps is empty, then x's suspension is returned; otherwise, a new suspension is created with those swaps.

```scheme
(define apply-π
  (λ (π v)
    (pmatch v
      (,c (guard (not (pair? c))) c)
      ((tie ,a ,t) (⋈ (apply-π π a) (apply-π π t)))
      ((nom _)
       (let loop ((v v) (π π))
         (cond
           ((null? π) v)
           (else (apply-swap (car π) (loop v (cdr π)))))))
      ((susp ,π̂ ,x)
       (let ((π '(,@π . ,π̂)))
         (if (null? π) (x) '(susp ,π ,x))))
      ((,a . ,d) '(,(apply-π π a) . ,(apply-π π d)))))))

(define apply-swap
  (λ (swap a)
    (pmatch swap
      ((,a₁ ,a₂)
       (cond
         ((eq? a a₂) a₁)
         ((eq? a a₁) a₂)
         (else a))))))
```

The ∇-*rules* are much simpler than the σ-*rules*. In the second clause, the nom $\hat{a}$ in the binding position of the binder is the same as a, so a can never appear free in t. In the fifth clause, the list of swaps $π$ in the suspension are applied, in reverse order, to the nom a, yielding another nom. ∇-*rules* then adds a new constraint associating this nom with the suspension's variable.

```scheme
(define ∇-rules
  (λ (d r)
    (pmatch d
      ((,a . ,c)
       (guard (not (pair? c)))
       '(,r ,empty-∇))
      ((,a . (tie ,â ,t))
       (guard (eq? â a))
       '(,r ,empty-∇))
      ((,a . (tie ,â ,t))
       (guard (not (eq? â a)))
       '(((,a . ,t) . ,r) ,empty-∇))
      ((,a . (nom _))
       (guard (not (eq? a (cdr d))))
       '(,r ,empty-∇))
      ((,a . (susp ,π ,x))
       '(,r (((,(apply-π (reverse π) a) . ,(x)))))
      ((,a . (,t₁ . ,t₂))
       (guard (untagged? t₁))
       '(((,a . ,t₁) (,a . ,t₂) . ,r) ,empty-∇))
      (else #f))))
```

Finding the disagreement set of two lists of swaps $π$ and $\hat{π}$ requires forming a set of all the noms in those lists, then applying both $π$ and $\hat{π}$ to each nom a in this set. If $(apply\text{-}π\ π\ a)$ and $(apply\text{-}π\ \hat{π}\ a)$ produce different noms, then a is in the *dis*agreement set.

```scheme
(define disagreement-set
  (λ (π π̂)
    (filter
      (λ (a) (not (eq? (apply-π π a) (apply-π π̂ a))))
      (remove-duplicates
        (append (apply append π) (apply append π̂))))))
```

(*filter* and *remove-duplicates* are defined in Appendix B.3.)

The $occurs^{\surd}$ is conventional, since even the suspension case is what one might expect.

```scheme
(define occurs√
  (λ (x v)
    (pmatch v
      (,c (guard (not (pair? c))) #f)
      ((tie _ ,t) (occurs√ x t))
      ((nom _) #f)
      ((susp _ ,x̂) (eq? (x̂) x))
      ((,x̂ . ,ŷ) (or (occurs√ x x̂) (occurs√ x ŷ)))
      (else #f))))
```

unify# is called by the # operator; it is similar to *unify* but only performs the second phase of nominal unification.

```scheme
(define unify#
  (λ (a t p)
    (call/cc
      (λ (fk)
        (mv-let ((σ ∇) p)
          (let ((δ '((,a . ,t))))
            (let* ((δ (apply-subst σ (δ-union ∇ δ)))
                   (∇ (apply-∇-rules δ fk)))
              '(,σ ,∇))))))))
```

4.1 Substitutions

compose-subst's definition is taken from Lloyd (1987). It takes two substitutions $σ$ and $τ$, and constructs a new substitution $\hat{σ}$ in which each association $(x\ .\ v)$ in $σ$ is replaced by $(x\ .\ \hat{v})$, where $\hat{v}$ is the result of applying $τ$ to v. Any association in $τ$ whose variable has an association in $\hat{σ}$ is then filtered from $τ$. Also, any association of the form $(x\ .\ x)$ is filtered from $\hat{σ}$. These filtered substitutions are then appended.

```scheme
(define compose-subst
  (λ (σ τ)
    (let ((σ̂ (map
               (λ (a) '(,(car a) . ,(apply-subst τ (cdr a))))
               σ)))
      (append
        (filter (λ (a) (not (assq (car a) σ̂))) τ)
        (filter (λ (a) (not (eq? (car a) (cdr a)))) σ̂)))))
```

Next we define *apply-subst*. In the suspension case, *apply-subst* applies the list of swaps $π$ to a variable, or to its binding.

```scheme
(define apply-subst
  (λ (σ v)
    (pmatch v
      (,c (guard (not (pair? c))) c)
      ((tie ,a ,t) (⋈ a (apply-subst σ t)))
      ((nom _) v)
      ((susp ,π ,x) (apply-π π (get (x) σ)))
      ((,x . ,y) '(,(apply-subst σ x) . ,(apply-subst σ y))))))
```

(*get* is defined in Appendix B.3.)

4.2 δ-union

Finally we define δ-*union*, which forms the union of two δ's.

```scheme
(define δ-union
  (λ (δ δ̂)
    (pmatch δ
      (() δ̂)
      ((,d . ,δ)
       (if (term-member? d δ̂)
           (δ-union δ δ̂)
           (cons d (δ-union δ δ̂)))))))
```

Recall that δ denotes a set of unprocessed constraints, where a constraint is a pair of a nom a and a term t. δ-*union* uses *term-member?*, which uses *term-equal?* when comparing two constraints. The definition of *term-equal?* is straightforward except when comparing two suspensions, in which case their variables must be the same, and the disagreement set of their lists of swaps must be empty.

```
(define term-member?
  (λ (v v*)
    (pmatch v*
      (() #f)
      ((,v̂ . ,v*)
       (or (term-equal? v̂ v) (term-member? v v*))))))

(define term-equal?
  (λ (u v)
    (pmatch `(,u ,v)
      ((,c ,ĉ) (guard (not (pair? c)) (not (pair? ĉ)))
       (equal? c ĉ))
      (((tie ,a ,t) (tie ,â ,t̂))
       (and (eq? a â) (term-equal? t t̂)))
      (((nom _) (nom _)) (eq? u v))
      (((susp ,π ,x) (susp ,π̂ ,x̂))
       (and (eq? (x) (x̂)) (null? (disagreement-set π π̂))))
      (((,x . ,y) (,x̂ . ,ŷ))
       (and (term-equal? x x̂) (term-equal? y ŷ)))
      (else #f))))
```

5. Conclusion

αKanren and αProlog, and perhaps to a lesser extent, MLSOS, are all based on the nominal logic programming paradigm. Nominal programming languages based on functional programming include FreshML (Shinwell et al. 2003) and Cαml (Pottier 2006).

We have presented an implementation of αKanren, an embedding of nominal logic programming in Scheme. αKanren allows programmers to easily write interpreters, type inferencers, and other programs that must reason about scope and binding. αKanren subsumes the functionality, syntax, and implementation of miniKanren, itself an embedding of logic programming in Scheme. Our goal in creating αKanren has been to make available a simple, concise, and readily understandable implementation of a nominal logic programming language in R^5RS Scheme. We hope that Scheme programmers will be inspired to use and extend αKanren, and in the process become familiar with the powerful tools provided by nominal logic.

A.   pmatch

In this appendix we describe **pmatch**, a simple pattern matcher written by Oleg Kiselyov. Let us first consider a simple example of **pmatch**.

```
(define h
  (λ (x y)
    (pmatch '(,x . ,y)
      ((,a . ,b) (guard (number? a) (number? b))
       (+ a b))
      (,c (guard (number? (cdr c)))
       (* (cdr c) (cdr c)))
      (else (* x x)))))
```

$(list\ (h\ 1\ 2)\ (h\ 'w\ 5)\ (h\ 6\ 'w)) \Rightarrow (3\ 25\ 36)$

In this example, a dotted pair is matched against three different kinds of patterns.

In the first pattern, the value of x is lexically bound to a and the value of y is lexically bound to b. Before the pattern match succeeds, however, an optional guard is run within the scope of a and b. The guard succeeds only if x and y are numbers; if so, then the sum of x and y is returned.

The second pattern matches against *any* value, provided that the optional guard succeeds. If so, the value of '$(,x\ .\ ,y)$ is lexically bound to c, and the square of y is returned.

If y is not a number, then the third and final clause is tried. An **else** pattern matches against *any* value, and never includes a guard. In this case, the clause returns the square of x, which must be a number in order to avoid an error at runtime.

Below is the definition of **pmatch**, which is implemented using continuation-passing-style macros (Hilsdale and Friedman 2000). The first clause ensures that the expression whose value is to be **pmatch**ed against is evaluated only once. The second clause returns an unspecified value if no other clause matches.

The remaining clauses represent the three types of patterns supported by **pmatch**. The first is the trivial **else** clause, which matches against any datum, and which behaves identically to an **else** clause in a **cond** expression. The other two clauses are identical, except that the first one includes a guard containing one or more expressions—if the datum matches against the pattern, the guard expressions are evaluated in left-to-right order. If a guard expres-

sion evaluates to **#f**, then it is as if the datum had failed to match against the pattern: the remaining guard expressions are ignored, and the next clause is tried.

The expression (fk) is evaluated if the pattern it is associated with fails to match, or if the pattern matches but the guard fails.

```
(define-syntax pmatch
  (syntax-rules (else guard)
    ((_ (op arg ...) cs ...)
     (let ((v (op arg ...)))
       (pmatch v cs ...)))
    ((_ v) (if #f #f))
    ((_ v (else e₀ e ...)) (begin e₀ e ...))
    ((_ v (pat (guard g ...) e₀ e ...) cs ...)
     (let ((fk (λ () (pmatch v cs ...))))
       (ppat v pat
         (if (and g ...) (begin e₀ e ...) (fk))
         (fk)))))
    ((_ v (pat e₀ e ...) cs ...)
     (let ((fk (λ () (pmatch v cs ...))))
       (ppat v pat (begin e₀ e ...) (fk))))))
```

ppat does the actual pattern matching over constants and pairs. The wild-card pattern _ matches against *any* value. The second pattern matches against the empty list. The third pattern matches against a quoted value. The fourth pattern matches against *any* value, and binds that value to a lexical variable with the specified identifier name. The fifth pattern matches against a pair, tears it apart, and recursively matches the *car* of the value against the *car* of the pattern. If that succeeds, the *cdr* of the value is recursively matched against the *cdr* of the pattern. (We use **let** to avoid building long *car/cdr* chains.) The last pattern matches against constants, including symbols.

```
(define-syntax ppat
  (syntax-rules (_ quote unquote)
    ((_ v _ kt kf) kt)
    ((_ v () kt kf) (if (null? v) kt kf))
    ((_ v (quote lit) kt kf)
     (if (equal? v (quote lit)) kt kf))
    ((_ v (unquote var) kt kf) (let ((var v)) kt))
    ((_ v (x . y) kt kf)
     (if (pair? v)
       (let ((vx (car v)) (vy (cdr v)))
         (ppat vx x (ppat vy y kt kf) kf))
       kf))
    ((_ v lit kt kf) (if (equal? v (quote lit)) kt kf))))
```

Here is the definition of h after expansion.

```
(define h
  (λ (x y)
    (let ((v '(,x . ,y)))
      (let ((fk (λ ()
                  (let ((fk (λ () (* x x))))
                    (let ((c v))
                      (if (number? (cdr c))
                        (* (cdr c) (cdr c))
                        (fk)))))))
        (if (pair? v)
          (let ((vx (car v)) (vy (cdr v)))
            (let ((a vx))
              (let ((b vy))
                (if (and (number? a) (number? b))
                  (+ a b)
                  (fk)))))
          (fk))))))
```

The **mv-let** macro, which deconstructs a list, can be defined using **pmatch**.

```
(define-syntax mv-let
  (syntax-rules ()
    ((_ ((x ...) e) b₀ b ...)
     (pmatch e ((,(x ...) b₀ b ...))))))
```

```
(mv-let ((x y z) '(1 2 3))
  (+ x y z))
```

⇒ 6

B. αKanren Implementation

Our αKanren implementation comprises three kinds of operators: the interface operator **run**; goal constructors ≡, #, cond^e, **exists**, and **fresh**, which take a package *implicitly*; and functions such as *reify*, and the already defined *unify* and *unify#*, which take a package *explicitly*.

A goal g is a function that maps a package p to an ordered sequence p^∞ of zero or more packages. (For clarity, we notate λ as λ_{G} when creating such a function g.)

```
(define-syntax λ_G
  (syntax-rules () ((_ (p) e) (λ (p) e))))
```

Because a sequence of packages may be infinite, we represent it not as a list but as a p^∞, a special kind of stream that can contain either zero, one, or more packages (Hinze 2000; Wadler 1985). We use **#f** to represent the empty stream of packages. If p is a package, then p itself represents the stream containing just p. To represent a stream containing multiple packages, we use (**choice** p f), where p is the first package in the stream, and where f is a thunk that, when invoked, produces the remainder of the stream. (For clarity, we notate λ as λ_{F} when creating such a function f.) To represent an incomplete stream, we use (**inc** e), where e is an *expression* that evaluates to a p^∞—thus **inc** creates an f.

```
(define-syntax λ_F
  (syntax-rules () ((_ () e) (λ () e))))
```

```
(define-syntax choice
  (syntax-rules () ((_ a f) (cons a f))))
```

```
(define-syntax inc
  (syntax-rules () ((_ e) (λ_F () e))))
```

A singleton stream p is the same as (**choice** p (λ_{F} () **#f**)). However, for the goals that return only a single package, using this special representation of a singleton stream avoids the cost of unnecessarily building and taking apart pairs, and creating and invoking thunks.

To ensure that the values produced by these four kinds of p^∞'s can be distinguished, we assume that a package is never **#f**, a function, or a pair whose *cdr* is a function. To discriminate among these four cases, we define **case$^\infty$**.

```
(define-syntax case^∞
  (syntax-rules ()
    ((_ a^∞ (() e₀) ((f̂) e₁) ((â) e₂) ((a f) e₃))
     (pmatch a^∞
       (#f e₀)
       (,f̂ (guard (procedure? f̂)) e₁)
       (,â (guard (not
                    (and (pair? â)
                         (procedure? (cdr â)))))
           e₂)
       ((,a . ,f) e₃)))))
```

The interface operator **run** uses *take* (defined below) to convert an f to an *even* stream (MacQueen et al. 1998). The definition of **run** places an artificial goal at the tail of g_0 g ...; this artificial goal reifies the variable x using the final package p produced by running the goals g_0 g ... in the empty package '(,*empty-σ* ,*empty-*$\overline{\nabla}$). Wrapping the reified value in a list allows **#f** to appear as a value without being interpreted as failure of the artificial goal; the *take* helper is responsible for unwrapping the reified value.

```
(define-syntax run
  (syntax-rules ()
    ((_ n (x) g₀ g ...)
     (take n (λ_F ()
               ((exists (x) g₀ g ...
                  (λ_G (p)
                    (cons (reify x p) '())))
                '(,empty-σ ,empty-∇)))))))
```

If the first argument to *take* is **#f**, then *take* returns the entire stream of reified values as a list, thereby providing the behavior of **run***. The **and** expressions within *take* detect this **#f** case.

```
(define take
  (λ (n f)
    (if (and n (zero? n))
        '()
        (case^∞ (f)
          (() '())
          ((f) (take n f))
          ((a) a)
          ((a f) (cons (car a)
                       (take (and n (− n 1)) f)))))))
```

run* is trivially defined in terms of **run**.

```
(define-syntax run*
  (syntax-rules ()
    ((_ (x) g₀ g ...)
     (run #f (x) g₀ g ...))))
```

We represent the empty substitution, along with the empty unprocessed and processed constraint sets, as the empty list.

```
(define empty-σ '())
```

```
(define empty-δ '())
```

```
(define empty-∇ '())
```

B.1   Goal Constructors

The simplest goal constructors are ≡ and #; the goals they create return either a singleton stream or an empty stream.

```
(define ≡
  (λ (u v)
    (λ_G (p)
      (unify u v p))))
```

```
(define #
  (λ (a t)
    (λ_G (p)
      (unify# a t p))))
```

To take the conjunction of goals, we define **exists**, a goal constructor that first lexically binds variables built by *var*, and then combines successive goals using **bind***. The goal constructor **fresh** is identical to **exists**, except that it lexically binds noms instead of variables.

```scheme
(define-syntax exists
  (syntax-rules ()
    ((_ (x ...) g₀ g ...)
     (λ_G (p)
       (inc
         (let ((x (var)) ...)
           (bind* (g₀ p) g ...)))))))

(define-syntax fresh
  (syntax-rules ()
    ((_ (a ...) g₀ g ...)
     (λ_G (p)
       (inc
         (let ((a (nom 'a)) ...)
           (bind* (g₀ p) g ...)))))))

(define nom
  (λ (a)
    `(nom ,(symbol→string a))))
```

bind is short-circuiting: since the empty stream is represented by **#f**, any failed goal causes **bind** to immediately return **#f**. **bind** relies on *bind* (Moggi 1991; Wadler 1992), which applies the goal *g* to each element in the stream p^∞. The resulting p^∞'s are then merged using *mplus*, which combines a p^∞ and an *f* to yield a single p^∞. (*bind* is similar to Lisp's *mapcan*, but instead of using *append* to combine lists of values, *bind* uses *mplus* to interleave the values of potentially infinite lists.)

```scheme
(define-syntax bind*
  (syntax-rules ()
    ((_ e) e)
    ((_ e g₀ g ...)
     (let ((a∞ e))
       (and a∞ (bind* (bind a∞ g₀) g ...))))))

(define bind
  (λ (a∞ g)
    (case∞ a∞
      (() #f)
      ((f) (inc (bind (f) g)))
      ((a) (g a))
      ((a f) (mplus (g a) (λ_F () (bind (f) g)))))))

(define mplus
  (λ (a∞ f)
    (case∞ a∞
      (() (f))
      ((f̂) (inc (mplus (f) f̂)))
      ((a) (choice a f))
      ((a f̂) (choice a (λ_F () (mplus (f) f̂)))))))
```

To take the disjunction of goals we define **cond**[e], a goal constructor that combines successive **cond**[e]-lines using **mplus**, which in turn relies on *mplus*. We use the same implicit package *p* for each **cond**[e]-line. To avoid unwanted divergence, we treat the **cond**[e]-lines as a single **inc** stream.

```scheme
(define-syntax cond^e
  (syntax-rules ()
    ((_ (g₀ g ...) (g₁ ĝ ...) ...)
     (λ_G (p)
       (inc
         (mplus*
           (bind* (g₀ p) g ...)
           (bind* (g₁ p) ĝ ...)
           ...))))))
```

```scheme
(define-syntax mplus*
  (syntax-rules ()
    ((_ e) e)
    ((_ e₀ e ...) (mplus e₀ (λ_F () (mplus* e ...))))))
```

For completeness, we define three additional αKanren goal constructors not used in this paper: **cond**[a] and **cond**[u], which can be used to prune the search tree of a program, and **project**, which can be used to access the values of variables. The examples from chapter 10 of *The Reasoned Schemer* (Friedman et al. 2005) demonstrate how **cond**[a] and **cond**[u] can be useful, and the pitfalls that await the unsuspecting reader.

```scheme
(define-syntax cond^a
  (syntax-rules ()
    ((_ (g₀ g ...) (g₁ ĝ ...) ...)
     (λ_G (p)
       (inc (if^a ((g₀ p) g ...)
                  ((g₁ p) ĝ ...) ...))))))
```

```scheme
(define-syntax if^a
  (syntax-rules ()
    ((_) #f)
    ((_ (e g ...) b ...)
     (let loop ((a∞ e))
       (case∞ a∞
         (() (if^a b ...))
         ((f) (inc (loop (f))))
         ((a) (bind* a∞ g ...))
         ((a f) (bind* a∞ g ...)))))))
```

```scheme
(define-syntax cond^u
  (syntax-rules ()
    ((_ (g₀ g ...) (g₁ ĝ ...) ...)
     (λ_G (p)
       (inc (if^u ((g₀ p) g ...)
                  ((g₁ p) ĝ ...) ...))))))
```

```scheme
(define-syntax if^u
  (syntax-rules ()
    ((_) #f)
    ((_ (e g ...) b ...)
     (let loop ((a∞ e))
       (case∞ a∞
         (() (if^u b ...))
         ((f) (inc (loop (f))))
         ((a) (bind* a∞ g ...))
         ((a f) (bind* a g ...)))))))
```

```scheme
(define-syntax project
  (syntax-rules ()
    ((_ (x ...) g₀ g ...)
     (λ_G (p)
       (mv-let ((σ ∇) p)
         (let ((x (get x σ)) ...)
           (bind* (g₀ p) g ...)))))))
```

B.2 Reification

reify takes a variable *x* and a package *p*, and returns the value associated with *x* in *p* (along with any relevant constraints), first replacing all variables and noms with symbols representing those entities. A constraint (*a . y*) is *relevant* if both *a* and *y* appear in the value associated with *x*. We call this process of turning an αKanren value into a Scheme value *reification*.

```scheme
(define reify
  (λ (x p)
    (mv-let ((σ ∇) p)
      (let* ((v (get x σ)) (s (reify-s v)) (v (walk* v s)))
        (let ((∇ (filter (λ (a)
                            (and (symbol? (car a))
                                 (symbol? (cdr a))))
                         (walk* ∇ s))))
          (cond
            ((null? ∇) v)
            (else '(,v : ,∇))))))))
```

The first **cond** clause returns only the reified value associated with x, when there are no relevant constraints. The **else** clause returns both the reified value of x and the reified set of relevant constraints; we have arbitrarily chosen the colon ':' to separate the reified value from the list of reified constraints.

$walk^*$ applies a special substitution s, which maps noms and variables to symbols, to an arbitrary value v.

```scheme
(define walk*
  (λ (v s)
    (pmatch v
      (,c (guard (not (pair? c))) c)
      ((tie ,a ,t) '(tie ,(get a s) ,(walk* t s)))
      ((nom ,n) (get v s))
      ((susp () _) (get v s))
      ((susp ,π ,x) '(susp ,(walk* π s) ,(get (x) s)))
      ((,a . ,d) '(,(walk* a s) . ,(walk* d s))))))
```

$reify-s$ is the heart of the reifier. $reify-s$ takes an arbitrary value v, and returns a substitution that maps every distinct nom and variable in v to a unique symbol. The trick to maintaining left-to-right ordering of the subscripts on these symbols is to process v from left to right, as can be seen in the last **pmatch** clause. When $reify-s$ encounters a nom or variable, it determines whether a mapping for that entity already exists. If not, $reify-s$ extends the substitution with an association between the nom or variable and a new, appropriately subscripted symbol.

```scheme
(define reify-s
  (letrec
    ((r-s (λ (v s)
            (pmatch v
              (,c (guard (not (pair? c))) s)
              ((tie ,a ,t) (r-s t (r-s a s)))
              ((nom ,n)
               (cond
                 ((assq v s) s)
                 (else
                  (let ((ok-nom? (nom-names-eq? n)))
                    (let ((rn (reify-n n ok-nom? s)))
                      (cons '(,v . ,rn) s))))))
              ((susp () _)
               (cond
                 ((assq v s) s)
                 (else
                  (let ((rn (reify-n "_" var? s)))
                    (cons '(,v . ,rn) s)))))
              ((susp ,π _) (r-s π s))
              ((,a . ,d) (r-s d (r-s a s)))))))
    (λ (v)
      (r-s v '())))))
```

```scheme
(define nom-names-eq?
  (λ (n)
    (λ (x)
      (pmatch x
        ((nom ,m) (string=? m n))
        (else #f)))))
```

```scheme
(define var?
  (λ (x)
    (pmatch x
      ((susp () _) #t)
      (else #f))))
```

$reify-n$ returns a symbol representing an individual variable or nom; this symbol always ends with a period followed by a non-negative integer.

```scheme
(define reify-n
  (λ (str pred s)
    (string→symbol
     (string-append str "."
       (cond
         ((assp pred s) ⇒
          (λ (p)
            (number→string (+ (num-of (cdr p)) 1))))
         (else "0"))))))
```

$reify-n$ uses $assp$ and $num-of$; $assp$ is like $assq$, except it is well defined for any unary predicate, while (num-of 'abc.52) returns the "subscript" 52. $num-of$ relies on the assumption that symbols representing noms do not contain periods.

```scheme
(define num-of
  (λ (a)
    (let ((c* (memv #\. (string→list (symbol→string a)))))
      (string→number (list→string (cdr c*))))))
```

B.3 Familiar Helpers

The auxiliaries below are generally useful functions that might be part of any library.

```scheme
(define get
  (λ (x s)
    (cond
      ((assq x s) ⇒ cdr)
      (else x))))
```

```scheme
(define assp
  (λ (p s)
    (cond
      ((null? s) #f)
      ((p (car (car s))) (car s))
      (else (assp p (cdr s))))))
```

```scheme
(define filter
  (λ (p s)
    (cond
      ((null? s) '())
      ((p (car s)) (cons (car s) (filter p (cdr s))))
      (else (filter p (cdr s))))))
```

```scheme
(define remove-duplicates
  (λ (s)
    (cond
      ((null? s) '())
      ((memq (car s) (cdr s)) (remove-duplicates (cdr s)))
      (else (cons (car s) (remove-duplicates (cdr s)))))))
```
